Abstract

The emergence of new network interface technology is enabling new approaches to the development of communications software. This paper evaluates the SHRIMP virtual memory mapped network interface by using it to build two fast implementations of remote procedure call (RPC).

Our first implementation, called vRPC*, is fully compatible with the* SunRPC *standard. We change the RPC runtime library; the operating system kernel is unchanged, and only a minimal change was needed in the stub generator to create a new protocol identifier. Despite these restrictions, our* vRPC *implementation is several times faster than existing* SunRPC *implementations. A round-trip null RPC with no arguments and results under* vRPC *takes about 33 microseconds.*

Our second implementation, called Shrimp RPC*, is not compatible with* SunRPC *but offers much better performance.* Shrimp RPC *specializes the stub generator and runtime library to take full advantage of SHRIMP's features. The result is a round-trip null RPC latency of 9.5 microseconds, which is about one microsecond above the hardware minimum.*

1 Introduction

Much is known about how to optimize remote procedure call (RPC) mechanisms on traditional workstation networks[2, 14, 17, 20]. The main effort in previous work was to reduce or avoid copying, to make traps and context switches fast, and to take advantage of common-case behavior. The emergence of new multiprocessor network interfaces opens new possibilities for constructing network software. It is not always clear, however, which interface is most appropriate for which task.

The SHRIMP project [6, 7] at Princeton University supports user level communication between processes by mapping memory pages between virtual address spaces. This Virtual Memory Mapped network interface seems to have many advantages including flexible user-level communication, and very low overhead to initiate data transfer.

In this paper we present two fast RPC libraries implemented using virtual memory mapped communication between user processes. The first one (*vRPC*) meets the *SunRPC* interface and achieves a round trip latency of 33 microseconds for a null call with no arguments, without compromising compatibility with the *SunRPC* standard. The server in *vRPC* can service at the same time clients using both the old (UDP- and TCP-based) and the new (SHRIMP-based) protocols. We implement two versions of *vRPC* for SHRIMP by rewriting *SunRPC* and taking advantage of the new features SHRIMP provides.

Our experiments with *vRPC* show that even without changing the stub generator or the kernel, RPC can be made several times faster on the new network interface than it is on conventional networks. *vRPC* outperforms by more than a factor of 4 the best, to our knowledge, reported implementation for fast networks [8], with a round trip time of about 33μs for a null RPC. Even greater gains could be achieved by applying well-known techniques that rely on changes to the stub generator.

The second library, *ShrimpRPC*, is a full-functionality RPC system but is not compatible with any standard. *ShrimpRPC* achieves a round trip latency of 9.5 microseconds, or about one microsecond above the hardware minimum for a round-trip communication. The *ShrimpRPC* library and stub generator are optimized to take advantage of SHRIMP.

In the remainder of the paper, we give some background information about SHRIMP and the new network interface in Sections 2 and 3. Section 4 gives an outline of *SunRPC*. Section 5 describes *vRPC* and presents measurements. *ShrimpRPC* is presented in section 6. Finally we compare the different transfer mechanisms provided by the SHRIMP hardware in the context of *vRPC* in Section 7, discuss related work in section 8, and draw conclusions in Section 9.

2 The SHRIMP network interface

The SHRIMP project at Princeton studies how to provide high-performance communication mechanisms to integrate commodity desktop systems such as PCs and workstations into inexpensive, high-performance multicomputers. End-to-end latency and bandwidth available to user processes are the primary performance metrics. The challenge is to provide a low-latency, high-bandwidth communication mechanism whose performance is competitive with or better than that of specially designed multicomputers.

The network interfaces of existing multicomputers and workstations require a significant amount of software overhead to implement message-passing protocols. The main reason for such high overheads is that these multicomputers use network interfaces that require a significant number of instructions at the operating system and user levels to provide protection, buffer management, and message-passing protocols. In these designs, communication is treated as a service of the operating system. This is expensive because it requires several crossings between user level and kernel level for each message, and also because it prevents applications from customizing their use of the communication hardware.

The computing nodes of SHRIMP are Pentium PCs, and the interconnection network is the same one used in the Intel Paragon. The key hardware component is the network interface board, which supports the virtual memory mapped communication (VMMC) model, to provide low-overhead, protected, user-level communication. For more details on the SHRIMP architecture the reader can consult [6, 7]. VMMC is discussed in the next section.

3 Virtual Memory-Mapped Communication

Virtual memory-mapped communication (VMMC) [10] was developed in response to the need for a basic multicomputer communication mechanism with extremely low latency and high bandwidth. These performance goals are achieved by allowing applications to transfer data directly between two virtual memory address spaces over the network. The basic mechanism is designed to efficiently support applications and common communication models such as message passing, shared memory, and client-server.

The VMMC mechanism consists of several calls to support user-level buffer management, various data transfer strategies, and transfer of control.

Import-Export Mappings In the VMMC model, an *import-export mapping* must be established before communication begins. A receiving process can *export* a region of its address space as a receive buffer together with a set of permissions to define access rights for the buffer. In order to send data to an exported receive buffer, a user process must *import* the buffer with the right permissions.

After successful imports, a sender can transfer data from its virtual memory into imported receive buffers at user-level without further protection checking or protection domain crossings. Communication under this import-export mapping mechanism is protected in two ways. First, a trusted daemon process implements import and export operations. Second, the hardware virtual memory management unit (MMU) on an importing node makes sure that transferred data cannot overwrite memory outside a receive buffer.

The *unexport* and *unimport* primitives can be used to destroy existing import-export mappings. Before completing, these calls wait for all currently pending messages using the mapping to be delivered.

Transfer Strategies The VMMC model defines two user-level transfer strategies: *deliberate update* and *automatic update*. Deliberate update is an explicit transfer of data from a sender's memory to a receiver's memory and can be either synchronous or asynchronous. In synchronous deliberate update the sender returns from the call only after the data are transferred in the network interface and it is safe to reuse the send buffers. In asynchronous deliberate update the sender returns immediately and can continue processing but it has to check later whether it is safe to reuse the send buffer.

In order to use automatic update, a sender *binds* a portion of its address space to an imported receive buffer, creating an *automatic update binding* between the local and remote memory. All writes performed to the local memory are automatically propagated to the remote memory as well, eliminating the need for an explicit send operation.

An important distinction between these two transfer strategies is that under automatic update, local memory is "bound" to a single receive buffer at the time a binding is created, while under deliberate update there is no fixed binding between a region of the sender's memory and a particular receive buffer. Automatic update is optimized for low latency, and deliberate update is designed for flexible import-export mappings and for reducing network traffic.

Automatic update is implemented by having the SHRIMP network interface hardware snoop all writes on the memory bus. If the write is to an address that has an automatic update binding, the hardware builds a packet containing the destination address and the written value, and sends it to the destination node. The hardware can combine writes to consecutive locations into a single packet.

Deliberate update is implemented by having a user-level program execute a sequence of two accesses to addresses which are decoded by the SHRIMP network interface board on the node's expansion bus (the EISA bus). These accesses specify the source address, destination address, and size of a transfer. The ordinary virtual memory protection mechanisms (MMU and page tables) are used to maintain protection [5].

VMMC guarantees the in-order, reliable delivery of all data transfers, provided that the ordinary, blocking version of the deliberate-update send operation is used. The ordering guarantees are a bit more complicated when the non-blocking deliberate-update send operation is used.

The VMMC model does not include any buffer management since data is transferred directly between user-level

address spaces. This gives applications the freedom to utilize as little buffering and copying as needed. The model directly supports zero-copy protocols when both the send and receive buffers are known at the time of a transfer initiation.

The VMMC model assumes that receive buffer addresses are specified by the sender, and received data is transferred directly to memory. Hence, there is no explicit receive operation. CPU involvement in receiving data can be as little as checking a flag, although a hardware notification mechanism is also supported.

Numbers for the latency and bandwidth delivered by the SHRIMP VMMC layer can be found in [13].

Notifications The *notification* mechanism is used to transfer control to a receiving process, or to notify the receiving process about external events. It consists of a message transfer followed by an invocation of a user-specified, user-level handler function. The receiving process can associate a separate handler function with each exported buffer, and notifications only take effect when a handler has been specified.

Notifications are similar to UNIX signals in that they can be blocked and unblocked, they can be accepted or discarded (on a per-buffer basis), and a process can be suspended until a particular notification arrives. Unlike signals, however, notifications are queued when blocked. Currently we have an implementation of notifications on top of UNIX signals, which works correctly but is slow. Soon, we expect to have an implementation similar to active messages [12], and thus to have much better performance than signals in the common case.

VMMC provides a call that allows a process to block until a notification arrives for it. When a process is waiting for a VMMC message to arrive, this call can be used to switch easily between spinning and blocking as appropriate.

4 SunRPC

SunRPC [19] is a widely used remote procedure call interface and specification. *SunRPC* consists of a set of library functions and a stub generator that follows the XDR [18] standard for data representation. *SunRPC* is a single thread implementation.

The general structure of *SunRPC* is shown in Figure 1. It is implemented as a series of layers, each providing services to the layers above.

- The *network* layer implements the `read` and `write` system calls that transfer data across the network.
- The *stream* layer does buffer management. It provides a set of functions to write data (byte strings, integers, etc.) to, or read data from, a stream. The stream layer hides the details of buffer management and network packet size from the higher layers. Its existence is very important to the performance of standard *SunRPC* implementations, since it reduces accesses to the expensive lower layers.

- The *XDR* [18] layer implements the XDR data representation specification, which insulates the higher layers from issues of machine-specific data representation. Data transferred between nodes in a network are translated to XDR format before sending, and translated back from XDR when received. The XDR layer provides a set of functions to send and receive data of a certain set of types: byte streams, longs, strings, unions etc.

- The RPC library implements most of the *SunRPC* protocol, including the management of client-server connections.

- The stub generator RPCGEN produces RPC stubs based on an interface definition supplied by the user.

As Figure 1 shows, the interface below the XDR layer separates the machine-dependent code from the machine independent layers.

Figure 1 also shows where copying takes place. Data is copied from the user buffers into the stream buffers and then passed to the operating system functions. In *SunRPC* there are two copies per side per RPC call at user level, plus the copies necessary at protection boundary crossings (one or two), and potentially copies in the kernel between kernel-driver buffers. These amount to a total of at least six copies per RPC call.

In the common execution path for an RPC, the client sends the header, the data and then waits for the reply. When the server replies the client receives first the header of the reply message and then the results. Because of the multiple layers, each call to XDR to send a datum results in a chain of several procedure calls.

5 vRPC

Our strategy in implementing *vRPC* on SHRIMP was to change as little as possible, and to remain fully compatible with existing *SunRPC* implementations. In order to meet these goals, we changed only the runtime library; we made minor changes to the stub generator[1] and we did not modify the kernel.

We used two main techniques to speed up the library. First, we re-implemented the network layer directly on top of the SHRIMP network interface. Because the SHRIMP interface is simple and allows direct user-to-user communication, our implementation of the network layer is much faster than the standard one. Our second optimization was to collapse the stream and SBL layers into a new single thin layer that provides the same functionality.

In the following paragraphs we describe the communication setup between the client and the server, we present *Direct vRPC*, *Reduced vRPC* and *Optimized vRPC* and we describe a modified version of *Optimized vRPC* that avoids copying on the receive side. Finally we summarize the different versions and we present measurements.

[1]We only added support for the new protocol, so that code for it is automatically generated.

Communication setup For *vRPC* a pair of mappings is established between every client and the server. Although creating mappings is expensive (relative to the very inexpensive communication) because exporting and importing buffers requires system calls, these operations are performed only once, during the initialization phase. In that sense RPC is a typical case of communications software where one can separate the expensive setup phase from the common case. The VMMC interface takes advantage of this.

The client and server use the normal portmapper interface for exporting and binding to services. After the client has found the port where the server is listening, the client establishes an ordinary Internet TCP connection as in *SunRPC*. This connection is used to exchange information about which VMMC buffers will be used. If the TCP connection breaks then each side assumes that the other side has terminated and the VMMC mappings are discarded. The existing TCP mechanism is a very convenient way to set up the communication channel and to detect failures. After the initialization phase no data is sent over the TCP channel.

Replacing the Network Layer One of our goals was to evaluate the performance gain to programs from eliminating kernel involvement in communication. Thus we first replaced the kernel layer with another, built on top of the VMMC interface, with almost no other changes to the code. This resulted to the first version of *vRPC*, *Direct vRPC*.

As mentioned before, the network layer provides a pair of functions (readtcp and writetcp) to read data from, and write data to, the network (via Internet-domain sockets). We replaced these two functions with our own versions (read_vmmc, write_vmmc) that send and receive data using VMMC between the server and the client. The following paragraphs describe the basic issues in the implementation of the new layer.

The *vRPC* communication layer consists of two functions that manage communication buffers. Transfers of data are performed using the VMMC communication mechanisms (*deliberate update and automatic update*). Receiving data does not require any explicit action, because the VMMC model delivers arriving data directly to memory with no CPU involvement. The number of copies on the sending and receiving sides depends on the mode of transfer and will be analyzed later.

The problems that need to be solved for buffer management are *synchronization,* which involves letting the receiver know about data arrival, and *flow control* for the finite shared buffer space.

Note that in the original implementation the network protocol stack took care of the corresponding problems at the lowest level (although at considerable cost).

Conceptually what is needed is a stream between the sender and the receiver. The sender sees only one end of the stream and the receiver the other. Each side sends or receives data without having to worry about the details of the underlying implementation.

This bidirectional VMMC stream consists of two low-level communication functions and a simple data structure.

A stream buffer has arbitrary size. The first two words of the buffer are reserved for protocol control information: a synchronization flag and a cursor to the end of valid data in the buffer.

A description of the protocol can be found in [3]. The low level stream protocol is implemented separately in both directions to form a bidirectional channel. The protocol allows the sender and the receiver to send and receive data with no handshaking as long as there is enough space. When the buffer is not full there is only one extra word of protocol information for each packet sent and no overhead for each packet consumed. When the buffer fills there is very little handshaking; one extra message sent from the receiver to the sender.

Waiting in the above protocol is implemented by spinning. Timeouts are used to avoid indefinite postponement. More sophisticated techniques for waiting are given in [15]. Blocking the server when there is no work to be done and then waking it up when a request arrives is not a problem, since the server will service all pending requests when it wakes up. Also a combination of spinning and blocking can be used to reduce response time on the server side. For instance the server can spin for a fixed amount of time before going to sleep.

To summarize, the first version of *vRPC*, *Direct vRPC*, replaces the stream layer with a simple stream communication abstraction implemented directly on top of the VMMC interface. The are still six copies per RPC. Elimination of kernel involvement in the communication path is the only difference from *SunRPC*. Figure 1 shows the overall structure of *vRPC*.

Collapsing Layers As noted above, in standard implementations of *SunRPC*, the stream layer is needed to decouple the XDR layer from the network layer, because calls to the network layer are expensive system calls. Now that the communication is done at user level there is no need for the stream layer. In fact, as we described above, the VMMC stream layer of *Direct vRPC* implements a stream. Eliminating the stream layer of *SunRPC* leads to the second version of *vRPC*, *Reduced vRPC*, as shown in Figure 1.

Apart from considerably reducing the layering overhead, this change also eliminates two copies per node per RPC. The only copies left are the transfers of data between library and user buffers on the receiving side. This copy is essential to maintain *SunRPC* semantics.

These two improvements, eliminating the overhead of a whole layer and avoiding copying, are due to

1. the low cost of the user level communication mechanisms which makes the extra stream layer unnecessary, and

2. the direct placement of data in virtual memory.

Moreover, the fact that the client and the server run on nodes of the same multiprocessor leads to two additional improvements. There is no need for translation of the data to and from an agreed transmission format. Also, authentication can be done once, when the SHRIMP connection is set up, rather than on every RPC.

Tuning vRPC *Reduced vRPC* is faster than any previous RPC implementation that we are aware of. We achieved this performance by merely porting and adapting existing code to the SHRIMP network interface. We can improve the performance further by tuning the RPC library for the SHRIMP and taking advantage of the *SunRPC* semantics and implementation.

In the protocol described above, each send operation consists of two parts: sending the data, and updating the control information in the low level protocol. Reducing the number of updates of the control information reduces the amount of data transferred but increases the latency of each transfer and reduces the amount of overlap between communication and computation. We modified *Reduced vRPC* to update the control information immediately after every data packet (in the stream protocol) is sent.

As mentioned above VMMC supports two different modes of transfer: deliberate update and automatic update. Performance can be improved by properly choosing when to use each mode. In *Direct vRPC* and *Reduced vRPC* we used synchronous deliberate update for all the transfers as a first approach. The use of synchronous deliberate update everywhere is overkill, since there are cases where it is guaranteed that the data will not be overwritten for some time. For example the header of the call will not be changed until the reply has arrived. The same is true for relatively small transfers. In the current implementation of *SunRPC* the client has to wait for a call to finish before proceeding with the next one. Using asynchronous deliberate update for almost all transfers is safe and increases overlapping of communication and computation.

Automatic update does not require any user code for initiation. The hardware detects accesses to the memory and performs the transfer to the corresponding remote location. This is a low latency mechanism that can be used for small transfers. Using automatic update for protocol control information further reduces the latency. An artifact of using automatic update to send the length is that asynchronous deliberate update cannot be used without extra synchronization, since automatic updates can overtake pending asynchronous deliberate updates, resulting in out of order data transfer.

Automatic update can operate in three different modes, with the mode setable on a per-page basis. It can either send each word of data immediately as a network packet (*single-write*), or accumulate writes into a single packet until a non-consecutive location is written (*block-write*), or accumulate writes until either a timeout occurs or a non-consecutive location is written (*timer-write*). Using block-write whenever more than one consecutive word is transferred in automatic update increases the bandwidth since one network header is used for more data and less processing is needed in the network interface for the same amount of data. However, single-write reduces the latency and is better for control information since these are single word transfers.

One more possible target for optimization is the function that performs the deliberate update. The ordinary library call to initiate a deliberate update send must check for errors (such as null pointers), and must break

transfers whenever they cross page boundaries. Since the *vRPC* library has more knowledge and has control over buffer allocation and data layout, a more lightweight form of the send function could be used.

We tuned *Reduced vRPC* to take advantage of these opportunities. This resulted in the final version of *vRPC*, *Optimized vRPC*, which uses single-write automatic update to transfer control information. For transferring data both synchronous deliberate update and block-write automatic update can be used.

No-copy vRPC implementation As mentioned above *Optimized vRPC* does one copy per side for a total of two per call (not counting the actual data transfers). It is possible to eliminate copies and have the data appear on the bus only during transfers across the nodes. This is a deviation from the initial constraint, that the stub generator should remain unchanged. Given the current implementation of *SunRPC* it is possible to avoid copying by either slightly modifying the stub generator or having the user modify the code that the generator produces. Only minor changes are required.

We modified *Optimized vRPC* to eliminate copying. In this version the server has to consume the data before the client is able to send more. This is already dealt with since the server has to finish processing the current call before going to the next. Problems could arise if the server keeps data across calls, but this is a highly unlikely case. Moreover this style of programming is not in line with the remote procedure call concept.

Summary To summarize, there are three versions of *vRPC*. In the first version, *Direct vRPC*, only the network layer is replaced, eliminating all system calls from the RPC path. The second version, *Reduced vRPC*, has a simpler structure, and involves considerably less copying. Finally the third version, *Optimized vRPC*, is tuned for the VMMC interface. We also have a modified *Optimized vRPC* that avoids copying at the cost of slightly deviating from the *SunRPC* standard.

Measurements Detailed performance numbers for *vRPC* and *SunRPC* can be found in [3]. Our experiments compare *SunRPC* and the three versions of *vRPC*. We divide the code into sections and present timing measurements for each section of the code, for null calls with six argument/result sizes: zero bytes, 8 bytes, 64 bytes, 256 bytes, 1440 bytes and 3K bytes. We measured 1000 calls in each case, eliminated outlying points (due to experiments being interrupted by system daemon activity, etc.) and then averaged over the remaining runs.

Figure 2 summarizes these results. It presents the round-trip time of a RPC call with different argument/result sizes for *vRPC* and SunRPC.

6 ShrimpRPC: A Specialized Implementation

While our *vRPC* library has very good performance, its implementation was limited by the need to remain compatible with the existing *SunRPC* standard. To explore the further performance gains that are possible, we implemented a non-compatible version of remote procedure call.

ShrimpRPC is not compatible with any existing RPC system, but it implements the full RPC functionality, with a stub generator that reads an interface definition file and generates code to marshal and unmarshal complex data types. The stub generator and runtime library were designed with SHRIMP in mind, so we believe they come close to the best possible RPC performance on the SHRIMP hardware.

Buffer Management The design of *ShrimpRPC* is similar to Bershad's URPC [1]; the main difference is that URPC runs on shared-memory machines while *ShrimpRPC* runs on the distributed-memory SHRIMP system. Each RPC binding consists of one receive buffer on each side (client and server) with bidirectional import-export mappings between them. When a call occurs, the client-side stub marshals the arguments into its buffer, and then transmits them into the server's buffer. At the end of the arguments is a flag which tells the server that the arguments are in place. The buffers are laid out so that the flag is in the same place for all calls that use the same binding, and so that the flag is immediately after the data. This allows both data and flag to be sent in a single data transfer.

When the server sees the flag, it calls the procedure that the client requested. At this point the arguments are still in the server's buffer. When the call is done, the server sends return values and a flag back to the sender.

Exploiting Automatic Update The structure of our *ShrimpRPC* works particularly well with automatic update. In this case, the client's buffer and the server's buffer are connected by a bidirectional automatic update binding; whenever one process writes its buffer, the written data is propagated automatically to the other process's buffer. The data layout and the structure of the client stub cause the client to fill memory locations consecutively while marshaling the arguments, so that all of the arguments and the flag can be combined into a single packet by the client-side hardware.

On the server side, return values (`OUT` and `INOUT` parameters) need no explicit marshaling. These variables are passed to the server-side procedure by reference: that is, by passing a pointer into the server's communication buffer. The result is that when the procedure writes any of its `OUT` or `INOUT` parameters, the written values are silently propagated back to the client by the automatic update mechanism. This communication is overlapped with the server's computation, so in many cases it appears to have no cost at all. When the server finishes, it simply writes a flag to tell the client that it is done.

The Stub Generator *ShrimpRPC* uses a specialized stub generator which is designed to make low-overhead stubs

that cause marshaled data to be laid out as described above. A description of the stub generator and examples of the data structures it produces can be found in [3].

Performance Figure 3 compares the performance of two versions of RPC: the *SunRPC*-compatible VRPC, and the non-compatible *ShrimpRPC*. We show the fastest version of each library, which uses automatic update in both cases.

The difference in round-trip time is more than a factor of three for small argument sizes: 9.5 μs for the non-compatible system, and 33 μs for the *SunRPC*-compatible system. The difference arises because the *SunRPC* standard requires a nontrivial header to be sent for every RPC, while the non-compatible *ShrimpRPC* system sends just the data plus a one-word flag, all of which can be combined by the hardware into a single packet. For large transfers, the difference is roughly a factor of two. This occurs because *ShrimpRPC* does not need to explicitly send the INOUT and OUT arguments from the server back to the client; these arguments are implicitly sent, in the background, via automatic update as the server writes them.

7 Implementation Tradeoffs

In addition to the algorithmic choices described so far, the performance of our RPC libraries also depends on the details of how we use the SHRIMP hardware. Two main decisions were required: whether to use deliberate update or automatic update, and how to configure the caches of the PC nodes. The two decisions are actually bound together, since the performance of deliberate update and automatic update transfers depend on caching.

Recall that deliberate update and automatic update use very different mechanisms to send data. Deliberate update performs a DMA transfer from memory across the I/O bus to the network interface board, while automatic update simply snoops values that are written on the memory bus.

Detailed micro-benchmarking of the SHRIMP system shows that, in most cases, deliberate update and automatic update achieve the same asymptotic bandwidth: about 23 MB/sec. The limiting factor in both cases is the rate at which packets can be transferred across the EISA I/O bus on the receiving side. However, there are some cases in which performance is worse.

To understand how this occurs, we must consider the cache architecture of the PCs. Each PC has an 8 kbyte, two-way associative first level cache, and a 256 kbyte, two-way associative second level cache. Both the first and the second level caches use write-through or write-back, depending on per-page state bits. Both caches use a line size of 32 bytes.

The hardware keeps the cache contents coherent with DMA transfers to and from memory. If DMA asks to read a memory location, and that location is dirty in the second-level cache, the cache writes the line back to memory

before the DMA read can proceed. If DMA asks to write a memory location, and that location is in the second-level cache, then the line is written back to memory if dirty, and in any case is invalidated in the caches, before the DMA write may proceed.

Because deliberate update does DMA reads from memory, its performance suffers when the data is dirty in the cache. At the beginning of each cache line in the transfer, the DMA engine is stalled while the line is written back from the cache to memory. When this occurs, deliberate update bandwidth degrades to 10 MB/sec.

One way to avoid this problem is to use write-through caching for the affected pages; write-through pages cannot be dirty in the cache. Unfortunately, if the application also uses these pages for computation, this will lead to increased memory bus traffic with lower overall performance.

Automatic update also suffers slightly when the source data is not in the caches. Our libraries implement bulk automatic update by doing a memory-to-memory copy from the source data location to an RPC buffer. If the source data is only in memory, then the copying code will take repeated cache misses, lowering the bandwidth to 20 MB/sec. Fortunately, this case appears to be rare.

These factors lead us to favor automatic update as a bulk transfer mechanism for our RPC libraries on the current SHRIMP system. On future machines, however, the conclusion may be different. The ratio of memory-bus speed to I/O bus speed may change. Future machines may not allow write-through caching, so automatic update pages will be forced to forgo caching altogether. Future systems will have more aggressive memory bus designs, so it will be harder to interface to the memory bus on a stock motherboard. Finally, different memory bus protocols may reduce or eliminate the DMA coherence penalty. We cannot predict which transfer mechanism will be better on future architectures.

8 Related Work

Our approach is similar in some ways to URPC [1], since both exploit user-level communication. URPC is built on top of a shared memory architecture while we use the distributed-memory SHRIMP architecture.

Bershad's LRPC [2] tries to optimize the kernel path for same-machine RPC calls. Since we have eliminated the kernel entirely, LRPC does not apply to our situation.

Thekkath and Levy [8] investigated the impact of recent improvements in network technology on communication software. They point out that both high throughput and low latency are required by modern distributed systems and that newer networks strive only for high throughput. They develop techniques to achieve low latency in communication software, using RPC as a case study. Their goal along with demonstrating the new techniques is to provide design guidelines for network controllers that will facilitate writing low latency communication software

in traditional architectures.

Active messages [12] are a restricted form of RPC, in which the server-side procedure may not perform any actions that might block. Active messages achieve performance similar to *ShrimpRPC* on high-performance hardware, but without allowing general handlers to be invoked. The Optimistic Active Messages [21] approach allows an arbitrary handler to be invoked, using a fast-path implementation but switching to a slower path if the handler blocks. Neither of these systems provides full RPC services, such as automatic stub generation or binding between untrusting parties.

Several papers (e.g. [14, 17]) describe optimizations that dramatically improve the performance of RPC in traditional systems. This is generally done by avoiding copying, and reducing context switching overhead and network and RPC protocol overhead.

9 Discussion and conclusions

Network interfaces can have a great impact on communication performance and ease of programming. User level communication and virtual memory mapped network interfaces embody many of the optimizations done in other systems at extra work. Simply modifying an existing communication library can give results close to or better than the most highly optimized version in traditional interfaces. Copying can be limited to a minimum, and there are no interrupts on packet receipt and no kernel intervention.

The VMMC interface reduces the user to user latency. Using low latency mechanisms and providing support for user level communication leads to high performance communication software.

This effort shows that new architectures can open new horizons to distributed programming by providing high performance at low implementation cost.

Acknowledgments

We are grateful to Cezary Dubnicki for his expert advice on the SHRIMP simulator [11], and for his implementation of the SHRIMP system software. We would also like to thank Liviu Iftode for his implementation of an early mini version of the system software. We thank the members of the SHRIMP team for many useful discussions during the course of this work.

This project is sponsored in part by ARPA under contract N00014-91-1-1144, by NSF under grant MIP-9420653, by Digital Equipment Corporation, and by Intel Corporation. Felten is supported in part by an NSF National Young Investigator Award.

Information about the Authors

Angelos Bilas received his B.Sc. degree in Computer Science from the Computer Engineering and Informatics Department, Patras University, Patras, Greece in 1993 and his M.A. degree in computer science from Princeton University. Currently, he is a Ph.D. student at Princeton University in the Department of Computer Science. His interests include distributed and parallel computing.

Edward W. Felten is Assistant Professor of Computer Science at Princeton University. He received his Ph.D. in Computer Science from the University of Washington in 1993. He received a National Young Investigator award from the National Science Foundation in 1994. His research interests include distributed and parallel computing and computer security.

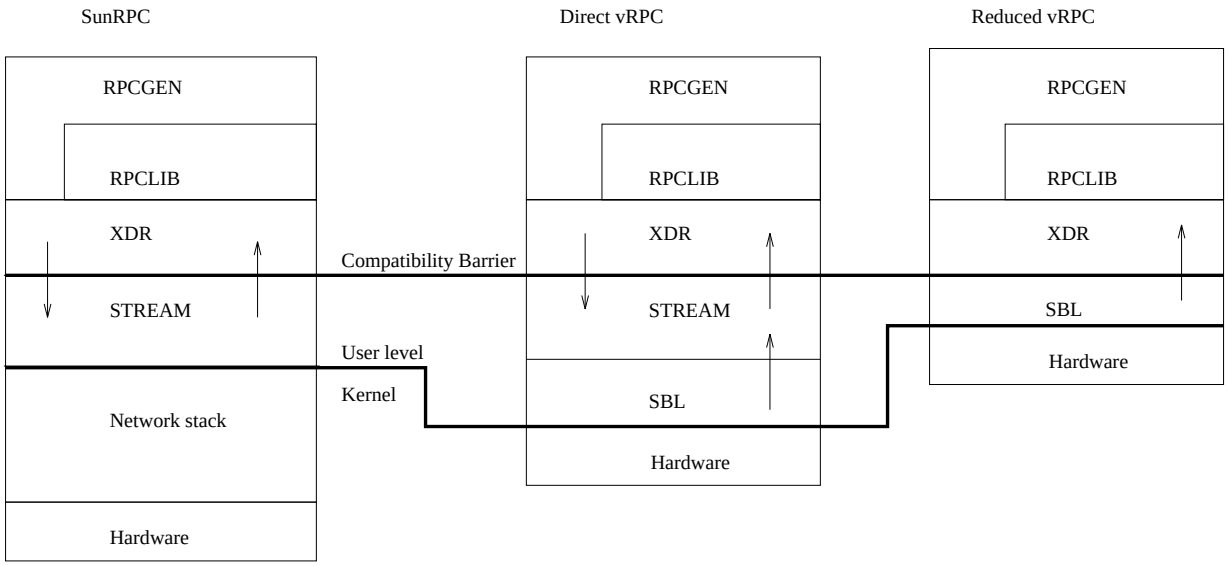

Figure 1: The structure of the different implementations. The arrows indicate the direction and number of copies at user level.

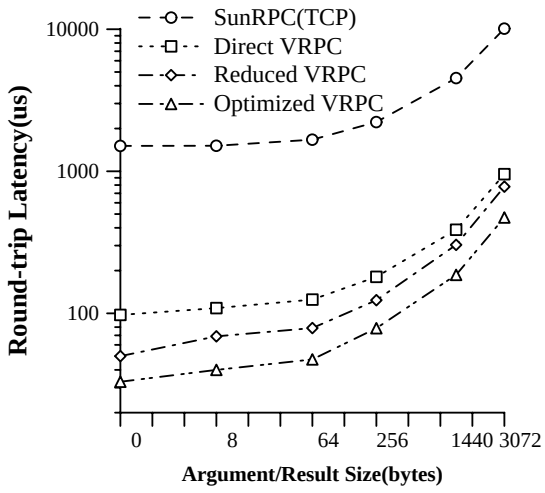

Figure 2: *SunRPC* and *vRPC* latency.

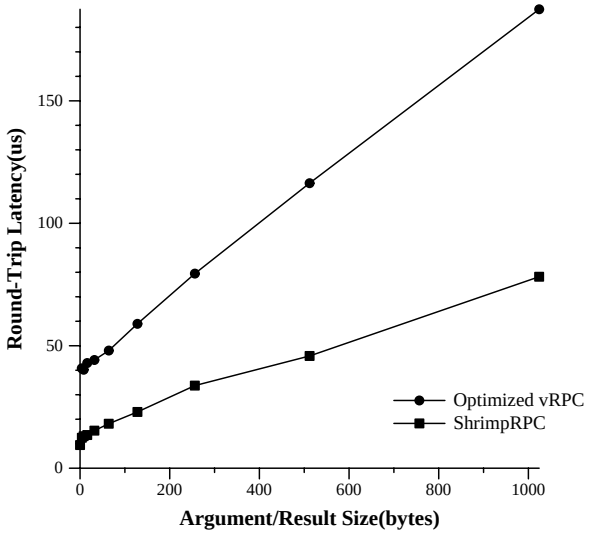

Figure 3: *Round-trip time for null RPC, with a single INOUT argument of varying size.*

Figure legends

The structure of the different implementations. The arrows indicate the direction and number of copies at user level.

SunRPC and *vRPC* latency.

Round-trip time for null RPC, with a single INOUT argument of varying size.
